Hedde Zeijlstra (Göttingen)

(Preliminary) Principles of Projection

Goetthe-Universität Frankfurt Workshop on agreement July 14, 2016

Question

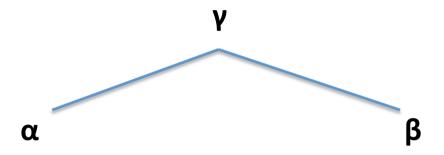

I. Question

What, if any, is the label of γ?

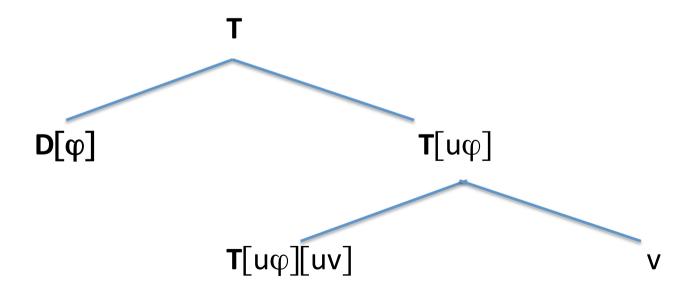

Is labelling required, and if so, is there a unified labeling algorithm that will suffice for all cases?

II. Previous approaches

Chomsky (1995, 2000), Adger (2003), Boeckx (2008): What selects projects.

• In $\{\alpha, \beta\}$, if α selects for (a feature present on) β , α is the label of $\{\alpha, \beta\}$.

II. Previous approaches

Advantages:

- Unified LA (except for adjunction): applies to Head-Comp configurations and to both internally and externally specifiers
- Determines the syntactic behaviour of the top node

II. Previous approaches

Problems:

- Unmotivated why the selector should project
- Does not apply to adjunction
- Ordering problem (why not have T first merge with DP and then with vP)?
- If selectional features are uninterpretable features, why can't they be checked on a distance?
- Various selectional features are taken to be semantic features (s-selection vs. c-selection). But why would semantic features play a role in syntax?
- What happens if the complement also selects a feature of the head (e.g. case feature checking to sisters of V or P)?

III. Aims

These problems (and other reasons) have called for various alternative approaches to labelling:

- Chomksy (1995, 2000, 2008): γ is either α or β
- Collins (2002): no label at all
- Adger (2012): something else than α or β
- Chomsky (2013, 2014): either α , β or a shared feature of α and β

III. Aims

But would it be possible to formulate a labelling theory based on the idea that selection projects that:

- Motivates why the selector projects
- Can account for labelling in all configurations (including adjunction)
- Can overcome the ordering problem
- Can account for the differences between selection and Agree
- Can circumvent the problems relating s-selection vs c-selection and mutual selection (e.g. with case)

Background

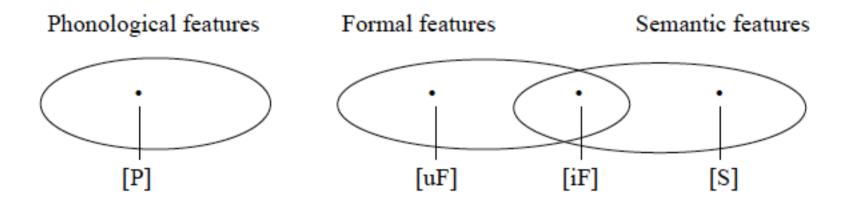

What features are involved in labelling and other syntactic operations?

- Chomsky (1995 et seq): minimally interpretable and uninterpretable formal features:
- Later on, a variety of other features have been postulated: categorial features, selectional features, edge features, EPPfeatures, fully uninterpretable features, etc.

Ideally, any theory of syntactic dependencies must be based on the smallest set of types of features: minimally, interpretable and uninterpretable formal features.

Chomsky (1995, 2000, 2001):

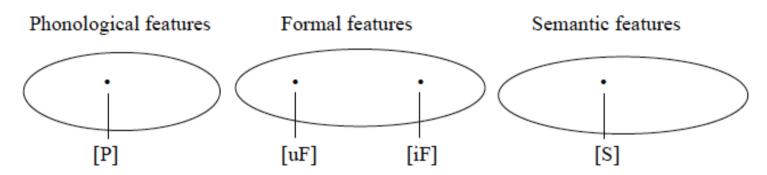

The set of formal features and the set of semantic features intersect:

 Uninterpretable features must be deleted under checking with interpretable features

Zeijlstra (2014):

• The sets of formal features and semantic features do not intersect:

- Language acquisition determines that most, but crucially not all, lexical items with the semantics of F are assigned a formal feature [iF].
- It is a property of syntax that [uF] features need to be cchecked by [iF] features (otherwise the sentence crashes).

Advantages:

- Interpretable features are no longer 'interpretable'; they are purely syntactic features.
- A better terminology would be dependent and independent features.
- If independent features are void of semantic content, they can be unified with categorial features.
- Lexical items then contain only two sets of features: dependent and independent categorial features:

Example: ON $\{\{[P]\},\{[uD]\}\}$

Proposal

Two approaches to the central question:

- Why should the top node receive some content (i.e. why must α or β percolate)?
- Why don't α and β not both percolate?

Most theories of labelling focus on the gain of information; hardly any theory focuses on the loss of information (Neeleman & Van der Koot 2002 being a notable exception).

Principle of Containment of Syntactic Information (CSI): syntactic information may not disappear in the tree (i.e. all syntactic features percolate).

 Merge results in the union of the sets of dependent and independent features of its daughters.

However, since both dependent and independent formal features are categorial features, merger of an element with a dependent and an element with a matching independent formal feature, results in removal of both:

$$\{\{[F]\}\}$$

$$\{\{[F]\}, \{[uG]\} \}$$

However, since both dependent and independent formal features are categorial features, merger of an element with a dependent and an element with a matching independent formal feature, results in removal of both:

Application

VI. Application

Now, let's see how the proposal deals with the desiderata for a labelling theory based on selectional projection:

- Motivates why the selector projects
- Can account for labelling in all configurations (including adjunction)
- Can overcome the ordering problem
- Can account for the differences between selection and agree
- Can circumvent the problems relating s-selection vs c-selection and mutual selection (e.g. with case)

The selector projects:

labelling of head-complement configurations and configurations involving specifiers

VI. Head-Complements

Given the categorial status of both dependent and independent features, sisterhood of two matching dependent and independent features results in removal of both from the top node.

This accounts for the fact that:

- The selected feature does not project
- the selecting feature does not project
- that all other features still project.

VI. Head-Complements

Example: D selecting NP

VI. Head-Complements

Example: P selecting DP

Following the earlier proposals, the same mechanism applies to specifiers merging with bar-levels.

Example: vP (involving External Merge):

$$\left\{ \left\{ [v] \right\} \right\}$$

$$\left\{ \left\{ [v] \right\}, \left\{ [uD] \right\} \right\}$$

$$\left\{ \left\{ [v] \right\}, \left\{ [uV], [uD] \right\} \right\}$$

Following the earlier proposals, the same mechanism applies to specifiers merging with bar-levels.

Example: TP (involving Internal Merge):

Hence, the proposal so far explains why the selector probes, and also how labeling works for Head-Complement relations and specifiers (irrespective of their original position).

 However, an problem for unifying labelling in both Head-Comp and Spec-Head configurations concerns the ordering of the fulfilment of the selectional requirements.

```
* {{[T]}}
{{[V]}}
{{[T]},{[uV]}}
{{[T]},{[uD],[uv]}}
```

Two solutions suggest themselves:

- Add ordering diacritics: for some reason, the [uv] feature on the T-head needs to be checked first, and only then the [uD] feature (same for [uV] and [uD] on v).
- Rule out the unwanted orders by means of interface conditions: the semantics of T require a semantic complement that can only be realized by vP, not by DPs; same for v.

Theoretical consequences:

- Apart from the addition of (ordering) diacritics, the first solution runs against the more central principle of the proposal, namely that the set of (in)dependent features present on a lexical item is unordered.
- Not immediately clear how every unwanted selection order can be ruled out, something required by the second solution.

Empirical consequences: the two solutions make a very clear empirical prediction:

- Under the ordered features solution flexible selection orders are never possible;
- Under the interface solution flexible selection orders are expected when the interfaces do not rule them out;

Spoiler: we will indeed attest cases where selection orderings are flexible.

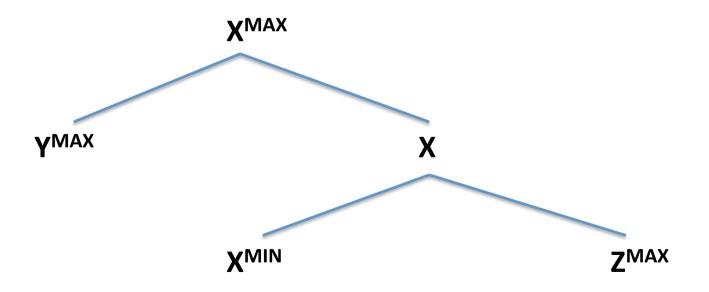

Adjunction

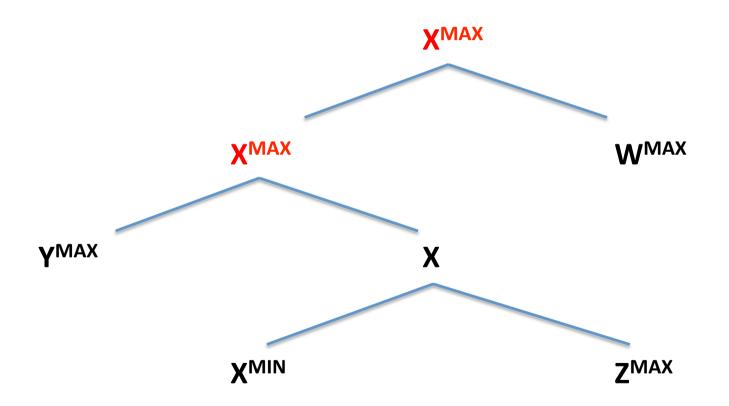

Adjuncts form a notorious problem for labelling under Bare Phrase Structure (cf. Hornstein & Nunes 2009 and references therein).

Under Bare Phrase Structure Bar levels and Maximal projections are structurally defined:

But adjunctions consists of two layers of the same feature that should both count as maximal:

For this reasons, adjuncts have been taken outside the system that derives structures by means of set-merge and labelling:

- Chomsky (2001): Set-Merge vs Pair-Merge
- Lebaux (1989): Late insertion of adjuncts into already labelled structures
- Hornstein & Nunes (2009): Unlabelled adjuncts

All these approaches have been primarily introduced to account for the special status of adjuncts under Bare Phrase Structure.

However, under the proposal proposed here, adjuncts can be derived under Bare Phrase Structure. Take the following structure

Irrespective of the phrasal status of the elements represented by $\{\{[X]\}\}$ and $\{\{[Y]\}\}$, we can compute the feature representation of the unknown sister/daughter, which must be:

Adjuncts are cases where the top node must be featurally identical to one its sisters, otherwise its distribution would not be identical.

But that means that every X-adjunct, should have a representation:

VIII. Adjuncts

VP adjuncts, e.g. adverbs, should then be taken to be elements with a featural representation $\{\{[V]\}, \{[uV]\}\}$.

But, as the picture shows, this solves the adjunct problem. In the configuration below, both V-layers are maximal projections (where colours show projection lines;

VIII. Adjuncts

Note that, as things stand now, adjuncts must be specified for the phrases they adjoin.

- For VP-adverbs we can indeed say that they are elements with a categorial feature set {{[V]}, {[uV]}}.
- But how about other types of adjuncts? Various adjuncts may modify different types of phrases, even phrases that belong to different extended projections.

The kind of adjuncts that are syntactically most flexible are PPs.

If PPs can be used as VP adjuncts, they should be analysed as $\{\{[V]\}, \{[uV]\}\}$. But such an analysis gives rise to the following two issues:

- If PPs are {{[V]}, {[uV]}}, what are Ps?
- PPs may adjoin to (at least) NPs, APs and VPs.

Let's discuss the two issues in turn.

Ps selecting DPs

If a PP is {{[V]}, {[uV]}}, then P must be: {{[V]}, {[uV], [uD]}}.

Ps selecting DPs

$$\{\{[V]\}, \{[uV]\}\}$$

$$\{\{[V]\}, \{[uV], [uD]\} \}$$

But now the ordering problem re-appears: why could P, then, not first select / merge with a V, and then with a DP? The proposal predicts the following to be grammatical:

But how bad are these structures?

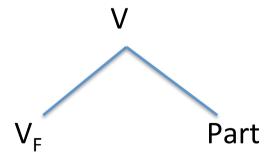

Many languages allow prepositions to form syntactic structures with verbs (so called particle verb constructions), before they merge with their arguments.

- [[Eat up] [the sandwich]]
- Ich rufe [Marie [an-rufe]] (German, I call Mary to)

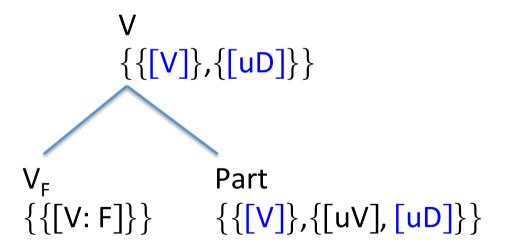

Even though such constructions are strongly constrained (not every preposition and verb can form a particle verb), the fact that some can shows that an analysis of prepositions being able to select verbs and jointly select a subsequent argument is necessary.

According to Van Riemsdijk (1978), Baker (1988), Koopman (1995), Neeleman (1994, 2002), Zeller (2001), among many others, particle verbs are complex verbal heads:

Zeller (2001): particle verbs are complex heads, where the verbal subfeatures of the verb do not percolate to the verbparticle complex (as only the verbal part can receive inflectional morphology):

This is indeed what is derived by the proposal: the verb is adjoined by the prepositional particle, but the verbal feature on the top node stems from the particle, not form the verb itself.

The existence of particle verbs

- thus supports the proposed analysis
- and forms an empirical argument for flexible selectional ordering, showing that constraints on sectional ordering must follow from the interfaces (with semantics) and not be encoded in syntax proper; when the interfaces do not rule out one of two logically possible orderings, both orderings are indeed ruled in.

The next question is how to deal with PPs modifying NPs and APs.

In principle PPs may modify NPs.

The book about Trump

 Also, (predicative) adjectives may be modified by PPs (albeit more rarely, presumably a consequence of the fact that most adjectives assign only one theta-role):

The doctor is afraid of the patient

*The afraid of the patient doctor committed suicide

If PPs (as any other adjuncts) select for their sisters, and PPs do not only select for verbs, there are two logical options:

- PPs are ambiguous between verbal, nominal and (predicatively used) adjectival PPs (and there are, thus, three types of prepositions).
- There is a supercategory above verbs, nouns and (predicatively used) adjectives.

The first option can hardly be supported as virtually every PP can be used to modify VPs, NPs and A_{Pred} Ps.

The second option, however, has been proposed for a variety of other reasons in the literature:

- In various languages various lexical items (if not all) can be used both verbally and nominally.
- The idea that lexical items are not stored in the lexical as nouns/verbs, but as roots, which are rendered nominal/verbal by having them merge with a N-/V- feature is very much in line with elements having some kind of a supercategorial feature.
- Semantically, verbs, nouns and adjectives all seem to denote predicates, with additional argumental or other requirements; this semantic core would then be reflected in the syntactic featural inventory.

Proposal:

- There is a superfeature [Predicate]
- This feature can receive a feature value (i.e. become a subfeature) V or N.
- Predicatively used adjectives are unvalued predicates.

[PRED(ICATE)]

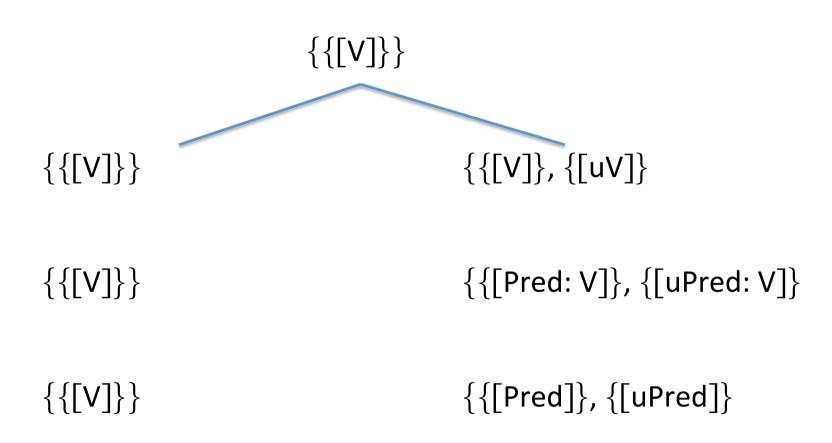

[PRED: N] = [N]

[PRED: V] = [V]

Now, if this is correct, Ps are nothing but elements that are:

- {{[PRED]},{[uPRED],[uD]}}
- Immediately valued for V/N (and thus become {{[V]},{[uV], [uD]}} and {{[N]},{[uN], [uD]}} respectively) when merged with a V- or N-labelled element.

V PP merger:

N PP merger:

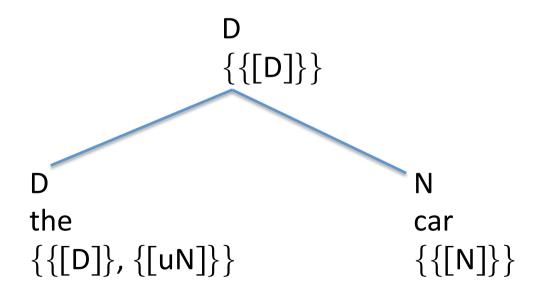

```
\big\{\big\{\big[N\big]\big\}\big\}
                                             {{[N]}, {[uN]}
\{\{[N]\}\}
\{\{[N]\}\}
                                             {{[Pred: N]}, {[uPred: N]}
\{\{[N]\}\}
                                             {{[Pred]}, {[uPred]}
```

If preprositions are indeed elements carrying {{[PRED]}, {[uPRED], [uD]}}:

- Their behaviour of PPs as N, V and A modifiers follows naturally.
- The analysis of adjuncts as elements selecting their modifiee can be maintained.
- It is shown that the set of selecting features ([uF]s) on a particular element should indeed remain unordered.

If predicative adjectives are indeed elements carrying $\{\{[PRED]\}\}$, questions concerning the internal structure of DPs arise .

Determiners select nouns, or nominal elements:

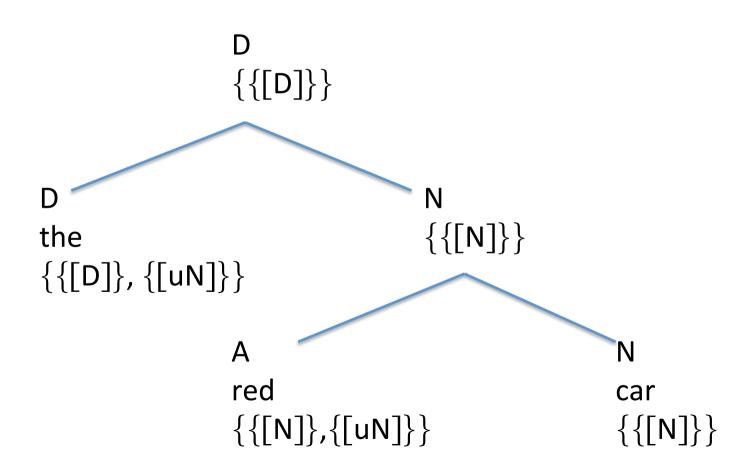

Under this system, proper names and pronouns are D-heads to do not select for any NPs.

- *John, Mary, the US*: {{[D]}}
- *They, her, we*: {{[D]}}

Two consequences:

- No need for a complex internal covert NP complex inside the DP (pace Abney 1997 et seq).
- (Interpretable) phi-features are hosted on D (and not on N).

But if Ds select NPs, nouns modified by (attributively used) adjectives must be NPs too.

But now we face a problem. If predicatively used adjectives are $\{\{[Pred]\}\}$, how can attributively used adjectives be $\{\{[N]\}\}$, $\{[uN]\}\}$?

 In some languages (e.g. Dutch) only attributively used adjectives receive morphological inflection, predicatively used adjectives do not.

De auto is rood/*rode
The car is red

De rode /*rood auto
The red.INFL car

Arguably, this shows that inflectional morphology on attributively used adjectives has a different formal function than that on predicatively used adjectives.

 This allows us to hypothesize that inflectional morphology on adjectives functions as a type-shifter: it changes predicates into nominal adjuncts.

```
N
                                \{\{[N]\}\}
          \mathsf{A}_{\mathsf{att}}
                                                                 N
          {{[N]},{[uN]}}
                                                                 auto
                                                                 \big\{\big\{\big[N\big]\big\}\big\}
Pred
                     Infl
Rood
{{[Pred]}} {{[N]},{[uPred],[uN]}}
```

Evidence for the idea that inflectional morphology changes predicates into nominal adjuncts comes again from PP modification.

 As in English, Dutch predicatively used adjectives can be modified by (right-adjoined) PPs; attributively used adjectives cannot be modified by (right-adjoined) PPs

De student is bang van Marie
The student is afraid of Marie
*De bang van Marie(-e) student
The afraid of Mary student

Evidence for the idea that inflectional morphology changes predicates into nominal adjuncts comes again from PP modification.

But attributively used adjectives can be modified by leftadjoined PPs:

> De van Marie bang-e student The of Mary afraid.INFL student

[De [[[van Marie bang]-e] student]]

Under this proposal, at least for some instances of inflectional morphology their presence can be motivated in formal terms (instead as some piece of redundant uninterpretable information).

- Moreover, note that this way, adverbs are the verbal counterparts of attributively used adjectives; they are elements carrying {{[V]},{[uV]}} that can be created in the same way from predicates.
- adverbial –ly would then just be {{[V]},{[uPred],[uV]}}: merged with a predicate like quick, this would then yield: quick-ly, carrying {{[V]},{[uV]}}.

Finally, one question needs to be addressed. If prepositions carry {{[Pred]},{[uPred],[uD]}}, motivated by their ability to modify nouns and verbs in the same way, why don't we have particle noun constructions?

*The in car seat (int.: the car-internal seat)

- The proposed system ruled this out. Apart from thetatheoretic requirements, in car seat would end up carrying {{[N]},{[uD]}}. But determiners carry {{[D]},{[uN]}}. Merger of these two would yield a label-less element.
- Of course merger of a proper name / pronoun and a particle noun construction should then be ruled out independently (in terms of semantic mismatches).

XII. Summing up

Summing up:

- In this way, the system meets several of the desiderata for any labelling account: it can account for all labelling configurations and it can circumvent the ordering problem.
- However, the difference between Agree and selection, as well as various issues concerning VP-internal labeling, are still in need of explanation.

Selection and Agree

XIII. Agree

So far, the system proposed exploits uninterpretable (or better: dependent) features to encode selectional requirements. But if (local) selection results from feature checking, how can Agree apply on a long distance?

 Proposal: Long-distance Agree is the result of local checking plus asymmetric feature percolation (cf. Neeleman & Van der Koot).

Currently: a debate about the directionality of Agree.

- Downward Agree (Chomksy 2001, Preminger 2013,
 Preminger & Polinsky 2015): an uninterpretable feature must c-command an interpretable matching feature.
- Upward Agree (Wurmbrand 2011, 2012, Zeijlstra 2012, Bjorkman & Zeijlstra 2015): an interpretable feature must ccommand an uninterpretable matching feature.

Major arguments come from different perspectives:

- Downward Agree: certain cases of long-distance agreement involve clear cases where the goal never c-commands the goal.
- Upward Agree: all syntactic dependencies (binding), strict NPI-licensing, Negative Concord, Sequence of Tense) except morphological co-varying phi-agreement involve clear 'upward' checking; long-distance agreement is often dependent on other instances of Upward Agree and defective.

Solution: separate valuation from checking (Bjorkman & Zeijlstra 2015)

- Checking: every uninterpretable feature must be checked by a c-commanding matching interpretable feature.
- Valuation: every unvalued feature must be valued; only if the checker does not value this feature itself, a lower interpretable feature can do this to (provided that this lower goal stands in a checking relation with the goal itself).

Examples: In languages with nominative-accusative case systems, agreement is with the subject.

•
$$[[DP_{NOM}]T_{[uPHI: _]}...[DP_{ACC}]]$$
 (English)

In languages with ergative-absolutive case systems, agreement is either with the subject or the object (cf. Bobaljik 2008). If ergative case is structural, the phi-features on the subject are active and can value the probe (e.g. Nepalese); if ergative case is inherent, these phi-features are inactive and the absolutive object (receiving case from T) fulfils the valuation requirement (e.g. Hindi)

So far:

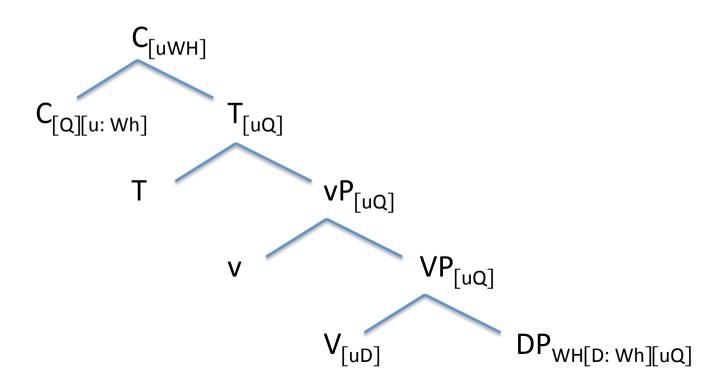

- Under this approach instances of downward agreement are compatible with the Upward Agree approach. For our purposes here, it suffices to say that every [uF] needs to be checked by a matching [F], the latter c-commanding the former.
- If valuation cannot take place under checking, another goal can complete the valuation process (under particular configurational conditions).

Now Agree (i.e. feature checking) is fully compatible with selection. Recall the Principle of Containment of Syntactic Information (CSI): syntactic information may not disappear in the tree (i.e. all syntactic features percolate).

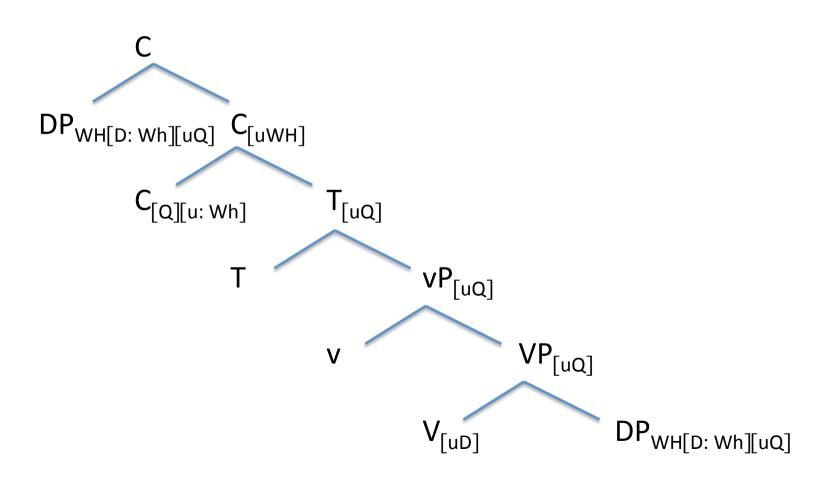

- By definition, interpretable features can never percolate beyond their maximal projection.
- Uninterpretable features always percolate up, until they stand in a sisterhood relation with a matching interpretable feature.

This derives Upward Agree!

Assume that all Wh-elements carry a feature [D: Wh] and a feature [uQ]; and that interrogative C carries a feature [uWh] and [Q]. Then, the Wh-elements can have its [uQ] feature checked off in situ by percolating it up till the C-level:

Movement is subsequently triggered by the need to check the higher [u: Wh] feature on C:

Summing up:

- The proposal is fully compatible with uninterpretable features triggering both selection and (Upward) Agree
- Upward Agree follows directly from the proposal (it was, in fact, developed as a motivation to derive the asymmetric nature of Upward Agree).
- Note: Agree is not the same as agreement; not every checker (fully) values its checkee; in those cases alternative, lower valuers may complete the valuation process.

So far, the proposal predicts that every selector forms the label. However, this is not particularly clear for VP-internal selection.

- Are the selectional requirements of a V s-selectional or c-selectional requirements? For this proposal it is necessary that V selects its arguments syntactically, not semantically.
 Otherwise the label of merger of V and D can never be V.
- How do case properties fill in? For this proposal, again, it is necessary that selected DPs do not check their selecting heads in return (as is often assumed in case theory).

Roadmap:

- Show that every V c-selects no more than one DP argument.
- Show that case requirements stem from the fact that Vs cannot select more than one DP argument.

The idea that verbs do not c-select, but rather s-select (DP) arguments comes from two reasons:

Vs often select non-DP arguments, but PP or CP arguments:

Mary knows Bill
Mary knows about Peter
Mary knows that Theo is ill

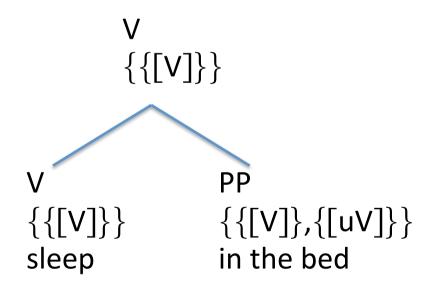

The idea that verbs do not c-select, but rather s-select (DP) arguments comes from two reasons:

Not every DP is selected as an argument

John works this week

As the latter type of argument could be analysed in terms of covert prepositions ($[_{PP} P [_{DP} this week]]$) (cf. Corver 2015), we focus on the first argument, which is generally taken to be the strongest argument against c-selection.

However, as shown before, PP arguments do not require any V to select them; PPs select VPs (or elements headed by [Pred] features).

In fact, even if V selects for a DP argument, it can be modified by a PP argument as well:

Under this proposal, Verbs do not syntactically select for PP arguments (or adjuncts), but they can be modified by PPs.

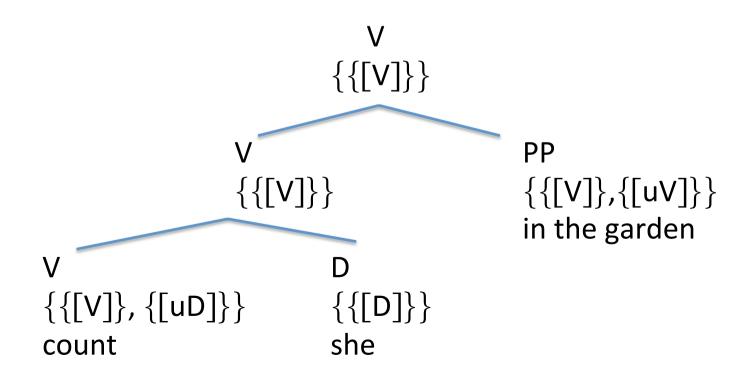

- PP arguments and PP adjuncts are syntactically identical; their differences follow from the (different) semantic properties of argument and adjunct PPs and the verb.
- At the same time the question arises if, and of so, how the argument-adjunct distinction of PPs is syntactically reflected.

PP adjuncts and PP arguments of a verb can be syntactically distinguished, as long as this verb also selects for a DP.

A PP sister of a verb behaves argumental if it is merged before the verb selects other arguments:

PP adjuncts and PP arguments of a verb can be syntactically distinguished, as long as this verb also selects for a DP.

A PP sister of a verb behaves adjunct-like if it is merged after the verb selects other arguments:

So, PPs do not form an argument against c-selection of Vs.

- Hence, the only argument against c-selection is the difference between DP arguments and CP arguments.
- In order to assess these differences, first it must be established what the syntactic features of CP arguments are.
- Most crucially, it should be determined what the differences and correspondences between (argument) CPs and (argument) DPs are.

Closer scrutiny shows that (argument) CPs share a number of prototypical properties of (argument) DPs.

- They control (3rd singular) agreement: That it rains is clear.
- They can be referred to by pronouns: That (John is ill) I know.
- They have case (in a clause with a CP subject, the DP receives dependent case): That Bill left Susanne shocked her.

Note that this not necessarily apply to every CP. It only holds for those CPs that can be used as (verbal) arguments.

CPs differ from DPs in the sense that complementizers select clauses (TP, vP, VP). Focusing on (argumental) *that*-CPs:

- That selects a TP
- The merger of that and a TP behaves like a DP
- On these grounds, it makes sense to think of complementizers like that as elements that change TPs into DPs. (Note that the pronominal nature of complementizers has been proposed earlier by Kayne 1994, among others).

Proposal: that carries {{[D]}, {[uT]}}.

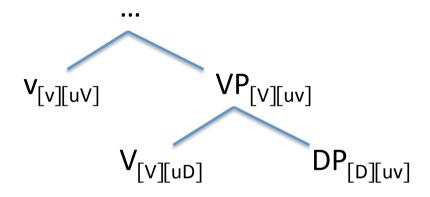

But this means that every verb that selects a DP or CP argument must carry [uD] (cf. Wurmbrand). The lexical semantics of these verbs determines whether the argument is an individual or a proposition.

- But now the question arises as to how verbs that select for multiple (DP) arguments encode these selectional properties
- In order to address this turn question it is necessary to discuss case.

The final desideratum for a labelling theory is how to deal with case. Under the Chomskyan view that case manifests an Agree relation between a DP and some (functional) head, our proposal faces severe problems.

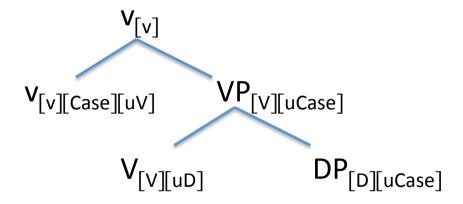

- To see this, assume that accusative case is [uv].
- Once [uv] is the sister of v (carrying [v]) their merger would be labelless:

The result would yield an element that lacks any (interpretable) feature:

■ Note that assigning v a [uD] feature would not solve the problem, as then merger with a DP would then render the merger labelless again.

Of course, this problem can be circumvented by ad hoc solutions; e.g., accusative reflects some feature [uCase] that at PF is realized as dependent accusative case:

But apart from lacking independent motivation, this solution is problematic for a number of other reasons.

- No principled motivation for [(u)Case] features
- Not clear whether case reflects Agree (cf. Marantz 1990, Baker 2015)
- No understanding why DPs should exhibit structural case in the first place.

Major problem for any case theory:

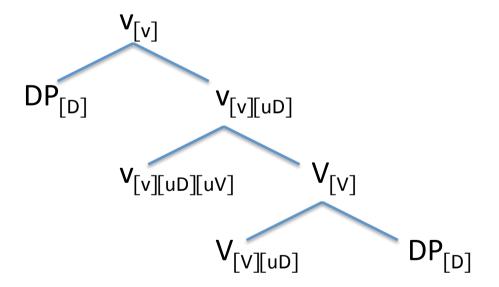

- Morphological case seems to be PF-determined (cf. Marantz 1990, Bobaljik 2008, Legate 2008).
- But DPs require licensing by some functional head (generally captured by syntactic Agree): structural case.
- Is there any way how the DP requirement to be licensed by a functional head can follow without encoding this in a direct feature-checking relation?

Answer: yes, there is. Let's solve this problem with the previous question: what happens with verbs selecting for multiple DP arguments.

- Suppose that a verb selects two DP arguments:
- Such a verb cannot carry two [uD]-features:

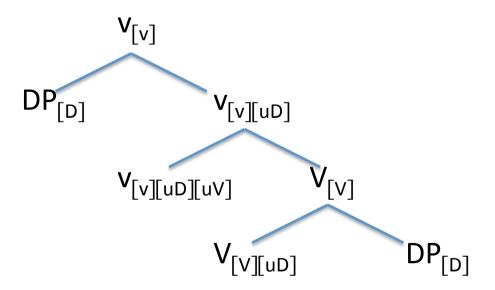

```
\{\{[V]\}, \{[uD], [uD]\}\} = \{\{[V]\}, \{[uD]\}\}
```

In order to be able to select for more than one DP argument, a verb needs to merge with another DP-selecting element (P or v):

Indeed, every licenser of structural case is a head that selects for (phi-valued) DPs: Finite T, v, P.

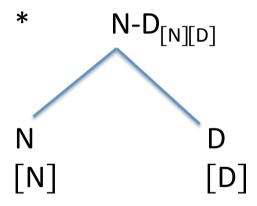

The function of introducing a head that can 'assign' structural case is nothing but selecting a new DP.

Structural case follows from the requirement that DPs need to be selected.

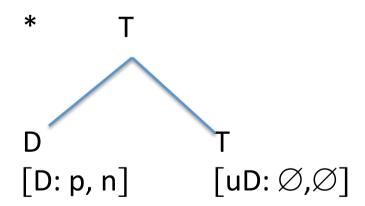

- Even if semantically a verb allows for multiple arguments, syntactically it cannot select multiple DPs, given that the set of selectional features is unordered.
- However, such an intuition of what is behind structural case is only valid if non-DP selecting elements cannot be merged with DP.

It needs to be prevented that DPs (and other elements) do not merge with elements that do not select them:

■ There are various ways of implementing this. The most straightforward one would be to allude to the more general constraint on Merge that it may only take place if it leads to feature checking (cf. Pesetsky & Torrego 2006, Wurmbrand 2014).

Finally, note that of structural case amounts to active phifeature values, every DP carrying structural case cannot be in the specifier of non-valued T (if non-finite T indeed means unvalued T):

■ Together, this yields the pattern that valued DPs must stand in a feature checking relation with either finite T, v or P, which is the classical structural case requirement.

Under this proposal, structural case is nothing but the requirement that every DP is to be selected, i.e. to be merged with, an element carrying [uD]. This correctly predicts that

- Every known 'case-assigner' (P, finite T, v) is an element selecting for DPs.
- DPs must Merge with these selectors.
- If the difference between elements carrying structural case and inherent case is that only elements with structural case have syntactically active phi-values, every agreement probe agrees with the closest DP 'carrying' structural case (cf. Bobaljik 2008).

Now we can also address the previous question: which verb select for DPs (i.e., carry a [uD] feature)?

- If all arguments need to be base-generated inside the VP; if every DP needs to be selected; and if every verb requires one DP subject, each verb must carry a feature [uD].
- Every transitive verb has an additional v-head, selecting a second (higher) argument.
- PP arguments are no arguments in the strict sense (but rather modifiers). Verbs with PP objects are strictly speaking intransitive. The structural position of a PP still determines its status of argument/adjunct.

This way, we even further conjecture that DP-selection is what renders a predicate being a verb.

Analogically, Nouns should then be predicates that select for finite tense (cf. Pesetsky & Torrego 2006):

But this potential extension is left for future work (with many other things).

Conclusions

XX. Conclusions

The proposal for a labelling algorithm:

- Motivates why the selector projects
- Can account for labelling in all configurations (including adjunction)
- Can overcome the ordering problem
- Can account for the differences between selection and agree
- Can circumvent the problems relating s-selection vs c-selection and mutual selection (e.g. with case)

XX. Conclusions

Moreover, it provides:

- A principled understanding of a syntax-internal labelling mechanism
- A motivation why Agree (in the sense of feature checking) applies in an upward fashion
- A motivation why DPs need to be licensed by functional heads (a.k.a. structural case)
- A severe reduction of the set of formal features (essentially T, D and Pred, and their underlying feature values)

THANK YOU!
